Abstract
In this article, we study the feasibility of dynamic longevity hedging with standardized securities that are linked to broad-based mortality indexes. On the technical front, we generalize the dynamic “delta” hedging strategy developed by Cairns (2011) to incorporate the situation when population basis risk exists. On the economic front, we discuss the potential financial benefits of an index-based hedge over a bespoke risk transfer. By considering data from a large group of national populations, we find evidence supporting the diversifiability of population basis risk. We further propose a customized surplus swap—executed between a hedger and reinsurer—to utilize the diversifiability. As standardized instruments demand less illiquidity premium, a combination of a dynamic index-based hedge and the proposed customized surplus swap may possibly be a more economical (and equally effective) alternative to a bespoke risk transfer.

Introduction
The market for longevity risk transfers started about 10 years ago. Since then, the market has seen some significant developments, most notably in terms of the number and size of deals (Blake et al., 2014). However, relative to the size of the global longevity risk exposure, the present longevity risk transfer market is still very small. A small market not only impedes longevity risk management, but also poses systemic concerns, because when longevity risk is shifted from the corporate sector to a limited number of (re)insurers, with global interconnections, there may be systemic

Kenneth Q. Zhou is a PhD Candidate in the Department of Statistics and Actuarial Science at the University of Waterloo, Canada. Johnny Siu-Hang Li holds the Fairfax Chair in Risk Management in the Department of Statistics and Actuarial Science at the University of Waterloo, Canada. Zhou and Li can be contacted via e-mail: kenneth.zhou@uwaterloo.ca and shli@uwaterloo.ca, respectively. The authors are grateful to the anonymous reviewers for their very constructive comments and suggestions. The authors would also like to thank participants at the Tenth International Longevity Risk and Capital Markets Solutions Conference for their stimulating discussions on an earlier version of this article. This work is supported by the Global Risk Institute, the Society of Actuaries Center of Actuarial Excellence Programme, and the Natural Sciences and Engineering Research Council of Canada (Discovery Grant RGPIN-356050-2013).
consequences in the case of a failure of a key player (Basel Committee of Banking Supervision, 2013).

The underdevelopment of the longevity risk transfer market may be attributed to the marked imbalance between demand and supply. To date, most of the longevity risk transfers executed are insurance based, typically in the form of pension buy-ins, pension buy-outs, or bespoke longevity swaps. While the insurance industry has the scope and financial stability to assume longevity risk, it does not generate sufficient supply for acceptance of the risk because of its capacity constraints. Using the assets for pension plans, in excess of 31 trillion USD, as a proxy for demand and the assets of 2.6 trillion USD held by the global insurance industry to cover nonlife risks as a proxy for supply, Graziani (2014) concludes that the demand for acceptance of longevity risk exceeds supply by a multiple of 10. Michaelson and Mulholland (2014) reach a similar conclusion by comparing the potential increase in pension liabilities due to unforeseen longevity improvement with the aggregate capital of the global insurance industry.

The growth of the longevity risk transfer market, therefore, depends highly on the creation of supply, most likely by inviting participation from capital markets, which are capable of assuming a larger portion of the longevity risk exposures from pension plans around the world.¹ The longevity asset class offers capital market investors a risk premium, plus potential diversification benefits due to its very low correlation with other asset classes. However, drawing interest from such investors requires the longevity risk transfer market to package the risk as standardized products that are structured like typical capital market derivatives and linked to broad-based mortality indexes. The act of standardization is important in part because it fosters the development of liquidity, and in part because it removes the information asymmetry arising from the fact that hedgers (pension plans) have better knowledge about the mortality experience of their own portfolios.

Toward the goal of standardization, the market for longevity risk transfers has to overcome two technical challenges that discourage hedgers from using standardized hedging instruments. The first challenge is to find out how standardized instruments can be used to form a hedge that can eliminate a meaningful portion of the hedger’s longevity risk exposure. Hedging strategies have to be developed so that hedgers know the type and notional amounts of hedging instruments they need to acquire. The second challenge is to understand and, more importantly, mitigate the residual risks that are left behind by a standardized, index-based longevity hedge. Of the residual risks the most significant constituent is population basis risk, which arises from the difference in future mortality improvements between the population associated with the hedger’s own portfolio and the population(s) to which the standardized instruments are linked. However, as explained below, the research questions on longevity hedging strategies and population basis risk are still open.

¹According to Roxburgh (2011), the total value of the world’s financial stock, comprising equity market capitalization and outstanding bonds and loans, is 212 trillion USD at the end of 2010.
A significant portion of the existing literature on longevity hedging strategies fo-
cuses on static hedging (Cairns et al., 2006; Cairns et al., 2014; Coughlan et al., 2011; 
Dowd et al., 2011; Li and Hardy, 2011; Li and Luo, 2012; Cairns, 2013). Static hedging 
strategies are generally subject to the shortcoming of the need for long-dated hedging 
instruments. For example, in an illustrative static hedge for a 30-year pension liabil-
ity, Li and Luo (2012) use five securities, of which the longest time to maturity is 25 
years. Such long-dated securities do not seem appealing to capital market investors. 
A few researchers, including Dahl (2004), Dahl and Møller (2006), Dahl, Melchior, and 
longevity hedging strategies. Except the work of Cairns (2011), the existing dynamic 
longevity hedging strategies were developed from continuous-time models, which 
provide mathematical tractability but are not straightforward to implement in prac-
tice. Further, although some existing static hedging strategies include an adjustment 
for population basis risk (Dowd et al., 2011; Li and Hardy, 2011; Li and Luo, 2012), 
none of the aforementioned dynamic longevity hedging strategies takes population 
basis risk into account.

For the problem of population basis risk, researchers have recently contributed sig-
nificantly to the development of multipopulation stochastic mortality models (Li and 
Lee, 2005; Cairns et al., 2011; Dowd et al., 2011; Jarner and Kryger, 2011; Li and Hardy, 
Zhou et al., 2014; Ahmadi and Li, 2014). Such models can be regarded as a prerequisite 
for understanding population basis risk, because they allow users to gauge the range 
of possible mortality differentials between two related populations, with biological 
reasonableness taken into consideration. Researchers have also introduced metrics 
for quantifying population basis risk, for example, reduction in expected shortfall 
(Ngai and Sherris, 2011), reduction in portfolio variance (Coughlan et al., 2011; Li and 
Hardy, 2011), and minimal required buffer (Stevens, Waegenaere, and Melenberg, 
2011). However, to our knowledge, little attention has been paid to how population 
basis risk can be mitigated.

In this article, we attempt to address the limitations of the current literature by inves-
tigating how a dynamic, index-based longevity hedge can be performed when pop-
ulation basis risk is present and how the residual risks left behind by the hedge can 
be mitigated. One part of the framework is a dynamic hedging strategy with which 
a pension plan can transfer the “trend risk” (i.e., the risk surrounding the trend in 
longevity improvement) to capital markets, even if the securities available are linked 
to a broad-based mortality index. Another part of the framework is a specially de-
gined reinsurance treaty, called a “customized surplus swap,” which transfers the 
residual risks to a reinsurer who collectively manages the residual risks from the 
index-based longevity hedges of various pension plans.2

The dynamic hedging strategy we propose is obtained by generalizing the dynamic 
“delta” hedging strategy of Cairns (2011) to incorporate the situation when the pop-

2A similar concept is mentioned by Cairns, Blake, and Dowd (2008). In their setup, hedgers 
transfer all their longevity risk exposures by writing bespoke longevity swaps with a special 
purposed vehicle (SPV), and the SPV in turn issues a standardized longevity bond that transfers 
the trend risk to bondholders. The residual risks are borne by the SPV manager.
ulations associated with the hedger’s portfolio and the hedging instruments are not the same. The generalization is derived on the basis of the augmented common factor (ACF) model (Li and Lee, 2005), under which the mortality dynamics of different populations are nontrivially correlated. Because the ACF model contains only one time-varying stochastic factor that is shared by all of the populations being modeled, the proposed hedging strategy requires the hedger to hold only one hedging instrument at a time. Also, because of dynamic adjustments, the hedging instrument used can be shorter dated. The former property helps the market to concentrate liquidity, while the latter property better meets the appetite of capital market investors. Adding further to the contribution of Cairns (2011) is a study of the robustness of the dynamic hedging strategy relative to different factors including model risk, small sample risk, and the properties of the hedging instruments used.

The customized surplus swap we design eliminates all residual risks that are left behind by the dynamic longevity hedge. Therefore, the combination of a dynamic longevity hedge and customized surplus swap should produce the same hedge effectiveness as a typical bespoke longevity swap. Using real mortality data from 25 different populations, we demonstrate that the residual risks can potentially be diversified away when a reinsurer writes customized surplus swaps with a range of hedgers. A reinsurer should, thus, have a much larger capacity to write customized surplus swaps than contracts such as pension buy-outs, which involve significant systematic risk. Overall, our proposed risk management framework is likely to be more economical than traditional longevity risk transfers that are entirely insurance based, because in theory it is less costly to transfer the systematic trend risk through liquidly traded standardized securities than tailor-made (re)insurance contracts.

The rest of this article is organized as follows. The “Dynamic Longevity Hedging Strategy” section presents the technical details of the proposed dynamic hedging strategy. The “Analyzing the Dynamic Longevity Hedge” section illustrates the proposed dynamic hedging strategy and evaluates its robustness relative to various factors. The “Managing the Residual Risks” section defines the proposed customized surplus swap and demonstrates the diversifiability of the residual risks. The last section concludes the article with some suggestions for future research.

**DYNAMIC LONGEVITY HEDGING STRATEGY**

The Assumed Model

The dynamic hedging strategy requires an assumed stochastic mortality model, from which quantities such as hedge ratios can be derived. In the single-population setup of Cairns (2011), the original Cairns–Blake–Dowd model (a.k.a. Model M5) was assumed. In our generalization, we assume the augmented common factor (ACF) model proposed by Li and Lee (2005). The ACF model concurrently models the mortality dynamics of multiple, say $P$, populations as follows:

$$\ln(m_{x,t}^{(i)}) = a_{x}^{(i)} + B_{i}K_{t} + b_{x}^{(i)}K_{t} + \epsilon_{x,t}^{(i)}, \quad i = 1, \ldots, P,$$

where $m_{x,t}^{(i)}$ represents population $i$’s central rate of death at age $x$ and in year $t$; $a_{x}^{(i)}$ is a parameter indicating population $i$’s average level of mortality at age $x$; $K_{t}$ is a time-
varying index that is shared by all \( P \) populations; \( k_t^{(i)} \) is a time-varying index that is specific to population \( i \); parameters \( B_x \) and \( b_{xt}^{(i)} \), respectively, reflect the sensitivity of \( \ln(m_{x,t}^{(i)}) \) to \( K_t \) and \( k_t^{(i)} \), and \( \epsilon_{st}^{(i)} \) is the error term that captures all remaining variations. The procedure we use to estimate the model is detailed in Online Appendix A.

The trend in \( K_t \) determines the evolution of mortality over time for all populations being modeled. As in the original Lee–Carter model (Lee and Carter, 1992), \( K_t \) is assumed to follow a random walk with drift: \( K_t = C + K_{t-1} + \xi_t \), where \( C \) is the drift term and \( \{\xi_t\} \) is a sequence of i.i.d. normal random variables with zero mean and constant variance \( \sigma_K^2 \).

Departures from the common time trend are captured by the population-specific index \( k_t^{(i)} \), which is assumed to follow a first-order autoregressive process: \( k_t^{(i)} = \phi_0^{(i)} + \phi_1^{(i)} k_{t-1}^{(i)} + \zeta_t^{(i)} \), where \( \phi_0^{(i)} \) and \( \phi_1^{(i)} \) are constants, and \( \{\zeta_t^{(i)}\} \) is a sequence of i.i.d. normal random variables with zero mean and constant variance \( \sigma_{k_t}^2 \). We require \( |\phi_1^{(i)}| < 1 \) so that the process for \( k_t^{(i)} \) is mean reverting. This property ensures that the resulting forecasts are coherent, which means the projected mortality rates for different populations do not diverge indefinitely over time. To incorporate any correlation that is not captured by the common trend \( K_t \), we further assume that \( \zeta_t^{(i)} \) and \( \zeta_t^{(j)} \) for \( i \neq j \) are constantly correlated, despite such correlations not being taken into account in the original ACF model.

The Setup

We let

\[
S_{x,t}^{(i)}(T) = \prod_{s=1}^{T} \left( 1 - q_{x+s-1,t+s}^{(i)} \right)
\]

(1)

be the ex post probability that an individual who is from population \( i \) and aged \( x \) at time \( t \) (the end of year \( t \)) would have survived to time \( t + T \), where \( q_{x,t}^{(i)} \) denotes the probability that an individual from population \( i \) dies between time \( t - 1 \) and \( t \) (during year \( t \)), provided that he/she has survived to age \( x \) at time \( t - 1 \). When computing \( q_{x,t}^{(i)} \) from \( m_{x,t}^{(i)} \) (on which the ACF model is based), we use the approximation \( q_{x,t}^{(i)} \approx 1 - \exp(-m_{x,t}^{(i)}) \). It is clear from the definitions that \( S_{x,t}^{(i)}(T) \) is not known prior to time \( t + T \), while \( q_{x,t}^{(i)} \) is not known prior to time \( t \).

Define by \( \mathcal{F}_t \) the information about the evolution of mortality up to and including time \( t \). Due to the Markov property of the assumed stochastic processes, the value of \( \mathbb{E}(S_{x,u}^{(i)}(T)|\mathcal{F}_t) \) for \( u \geq t \) depends only on the values of \( K_t \) and \( k_t^{(i)} \) but not the values of \( K_v \) and \( k_v^{(i)} \) for \( v < t \). Hence, we have

\[
p_{x,u}^{(i)}(T,K_t,k_t^{(i)}) := \mathbb{E} \left( S_{x,u}^{(i)}(T)|K_t,k_t^{(i)} \right) = \mathbb{E} \left( S_{x,u}^{(i)}(T)|\mathcal{F}_t \right).
\]

We call \( p_{x,u}^{(i)}(T,K_t,k_t^{(i)}) \) a spot survival probability when \( u = t \) and a forward survival probability when \( u > t \).
Let us suppose that the hedger intends to hedge the longevity risk associated with a pension plan for a single cohort of individuals, who are all from population $H$ and aged $x_0$ at time 0. The plan pays each pensioner $1 at the end of each year until death. It follows that the time $t$ value of the pension plan’s future liabilities (per surviving pensioner at time $t$) can be expressed in terms of spot survival probabilities as

$$FL_t = \sum_{s=1}^{\infty} (1 + r)^{-s} p_{x_0+t,s}^{(H)} \left( s, K_t, k_t^{(H)} \right),$$

where $r$ is the interest rate for discounting purposes.

The hedging instruments are q-forwards that are associated with population $R$. A q-forward is a zero-coupon swap with its floating leg proportional to the realized death probability at a certain reference age during the year immediately prior to maturity and its fixed leg proportional to the corresponding predetermined forward mortality rate. In this application, the hedger should participate in the q-forwards as the fixed-rate receiver, so that he/she will receive a net payment from the counterparty when mortality turns out to be lower than expected.

Consider a q-forward that is linked to reference population $R$ and age $x_f$. Suppose that the q-forward is issued at time $t_0$ and matures at time $t_0 + T^*$. The payoff from the q-forward depends on the realized value of $q_{x_f,t_0+T^*}^{(R)}$. The corresponding forward mortality rate $q_f$ is chosen so that no payment exchanges hands at inception (time $t_0$). It is assumed that $q_f = E(q_{x_f,t_0+T^*}|\mathcal{F}_{t_0})$, which is equivalent to saying that no risk premium is given to the counterparty accepting the risk. At $t = t_0, \ldots, t_0 + T^* - 1$, the value of the hedger’s position of the q-forward (per $1 notional) can be expressed as

$$Q_t(t_0) = (1 + r)^{-(t_0+T^*-t)} \left( q_f - E \left( q_{x_f,t_0+T^*}|\mathcal{F}_t \right) \right)$$

$$= (1 + r)^{-(t_0+T^*-t)} \left( q_f - \left( 1 - E \left( s_{x_f,t_0+T^*-1}^{(R)}(1)|\mathcal{F}_t \right) \right) \right)$$

$$= (1 + r)^{-(t_0+T^*-t)} \left( q_f - \left( 1 - p_{x_f,t_0+T^*-1}(1, K_t, k_t^{(R)}) \right) \right).$$

Under our pricing assumption, we have $Q_{t_0}(t_0) = 0$. Note that both $FL_t$ and $Q_t(t_0)$ are related linearly to values of $p_{x,u}^{(i)}(T, K_t, k_t^{(i)})$, where $i = H, R$ and $u \geq t$.

---

3Because the counterparty accepting longevity risk from the hedger deserves a risk premium, in practice $q_f$ should be smaller than $E(q_{x_f,t_0+T^*}|\mathcal{F}_{t_0})$, so that payoff to the counterparty is positive in expectation terms. However, because our focus for now is the technical aspects rather than the associated costs, we assume $q_f = E(q_{x_f,t_0+T^*}|\mathcal{F}_{t_0})$ for simplicity.
Because to reduce computation burden, in the next subsection we derive formulas to approximate.

Partial derivatives with respect to $K_t$ and $\partial f_{x,t}(T, K_t, k_t^{(i)})$ for $u \geq t$ (and thus $FL_t$ and $Q_t(t_0)$) cannot be computed analytically. It follows that nested simulations are required, making the dynamic hedging framework strategy computationally challenging.

In more detail, let us assume that the hedging horizon is $Y$ years and that the q-forward portfolio is adjusted annually. Suppose that $N$ sample paths of future mortality (i.e., values of $K_t$, $k_t^{(H)}$, and $k_t^{(R)}$ for $t = 1, \ldots, Y$) are used to evaluate the hedge’s performance. For each of these $N$ sample paths, we need to evaluate, at each time point $t$ for $t = 1, \ldots, Y$, $FL_t$ and $Q_t(t_0)$ on the basis of the realized values of $K_t$, $k_t^{(H)}$ and $k_t^{(R)}$ in that particular sample path. If we calculate each $FL_t$ and $Q_t(t_0)$ with $M$ sample paths of mortality beyond time $t$, then in total we need to generate $N \times M \times Y$ sample paths. Because $N$ and $M$ are typically very large, say 10,000, the computational burden is huge.

To reduce computation burden, in the next subsection we derive formulas to approximate $p_{x,u}^{(i)}(T, K_t, k_t^{(i)})$ for $u \geq t$ so that the need for some of the simulations can be avoided. The accuracy of the approximation formulas is evaluated in Online Appendix B.

The Approximation Methods

The approximation formula for $p_{x,u}^{(i)}(T, K_t, k_t^{(i)})$ depends on whether $u = t$ or $u > t$.

**Approximating $p_{x,u}^{(i)}(T, K_t, k_t^{(i)})$ When $u = t$.** Following Cairns (2011), we approximate $p_{x,t}^{(i)}(T, K_t, k_t^{(i)})$ by applying a Taylor expansion to its probit transform, $f_{x,t}^{(i)}(T, K_t, k_t^{(i)}) := \Phi^{-1}(p_{x,t}^{(i)}(T, K_t, k_t^{(i)}))$, where $\Phi$ denotes the standard normal distribution function. The Taylor expansion is made around $\hat{K}_t = E(K_t | K_0)$ and $\hat{k}_t^{(i)} = E(k_t^{(i)} | k_0^{(i)})$. We consider a second-order approximation, $f_{x,t}^{(i)}(T, K_t, k_t^{(i)}) \approx \tilde{f}_{x,t}^{(i)}(T, K_t, k_t^{(i)})$, where

$$\tilde{f}_{x,t}^{(i)}(T, K_t, k_t^{(i)}) := D_{x,t,0}^{(i)}(T) + D_{x,t,1}^{(i)}(T) \left( K_t - \hat{K}_t \right) + D_{x,t,2}^{(i)}(T) \left( k_t^{(i)} - \hat{k}_t^{(i)} \right)$$

$$+ \frac{1}{2} D_{x,t,3}^{(i)}(T) \left( K_t - \hat{K}_t \right)^2 + \frac{1}{2} D_{x,t,4}^{(i)}(T) \left( k_t^{(i)} - \hat{k}_t^{(i)} \right)^2$$

$$+ D_{x,t,5}^{(i)}(T) \left( K_t - \hat{K}_t \right) \left( k_t^{(i)} - \hat{k}_t^{(i)} \right),$$

and

$$D_{x,t,0}^{(i)}(T) = f_{x,t}^{(i)}(T, \hat{K}_t, \hat{k}_t^{(i)}), \quad D_{x,t,1}^{(i)}(T) = \frac{\partial f_{x,t}^{(i)}(T, K_t, k_t^{(i)})}{\partial K_t} \bigg|_{K_t=\hat{K}_t},$$

$$D_{x,t,2}^{(i)}(T) = \frac{\partial f_{x,t}^{(i)}(T, K_t, k_t^{(i)})}{\partial k_t^{(i)}} \bigg|_{K_t=\hat{K}_t},$$

$$D_{x,t,3}^{(i)}(T) = \frac{\partial^2 f_{x,t}^{(i)}(T, K_t, k_t^{(i)})}{\partial K_t^2} \bigg|_{K_t=\hat{K}_t},$$

$$D_{x,t,4}^{(i)}(T) = \frac{\partial^2 f_{x,t}^{(i)}(T, K_t, k_t^{(i)})}{\partial (k_t^{(i)})^2} \bigg|_{K_t=\hat{K}_t},$$

$$D_{x,t,5}^{(i)}(T) = \frac{\partial^2 f_{x,t}^{(i)}(T, K_t, k_t^{(i)})}{\partial K_t \partial (k_t^{(i)})} \bigg|_{K_t=\hat{K}_t}.$$
Approximating $p_{N}$

Suppose again that $N$ mortality scenarios are used to evaluate the hedge’s performance. Because the partial derivatives are independent of these scenarios, the total number of sample paths we need to generate is $9 \times M \times Y$.

Suppose again that $N$ mortality scenarios are used to evaluate the hedge’s performance. Because the partial derivatives are independent of these $N$ mortality scenarios, the total number of sample paths we need to generate is $N + 9 \times M \times Y$, which is significantly smaller than $N \times M \times Y$ when $N$ and $M$ are large.

**Approximating $p_{x,u}^{(i)}(T, k_{t}, k_{i}^{(i)})$ When $u > t$.** Using a first-order approximation, it can be shown that

$$p_{x,u}^{(i)}(T, k_{t}, k_{i}^{(i)}) \approx \Phi \left( \frac{-E(V_{u}^{(i)}|F_{t})}{\sqrt{Var(V_{u}^{(i)}|F_{t})}} \right).$$

A proof of the above approximation formula and the expressions for $E(V_{u}^{(i)})$ and $Var(V_{u}^{(i)}|F_{t})$ are provided in Online Appendix C.

**Deriving Hedge Ratios**

Our goal is to ensure that at each discrete time point $t$, the q-forward portfolio and the pension plan’s future liabilities have similar sensitivities to changes in the underlying common mortality index $K_{t}$. To achieve this goal, the hedge ratio $h_{t}$ (i.e., the notional amount of the q-forward) at time $t$ is chosen in such a way that

$$\frac{\partial f_{t}}{\partial K_{t}} = h_{t} \frac{\partial Q_{t}(l_{0})}{\partial K_{t}}.$$
In the rest of this article, it is assumed (e.g., the M-CBD model described in Online Appendix D), then the delta hedge would require more than one q-forward.

The partial derivative of $FL_t$ with respect to $K_t$ is computed as follows:

$$
\frac{\partial FL_t}{\partial K_t} = \sum_{s=1}^{\infty} (1 + r)^{-s} \frac{\partial \Phi^{(H)}_{x_0 + t, t} \left(s, K_t, k_t^{(H)}\right)}{\partial K_t}
$$

$$
= \sum_{s=1}^{\infty} (1 + r)^{-s} \frac{\partial \left(f^{(H)}_{x_0 + t, t} \left(s, K_t, k_t^{(H)}\right)\right)}{\partial K_t}
$$

$$
\approx \sum_{s=1}^{\infty} (1 + r)^{-s} \phi \left(f^{(H)}_{x_0 + t, t} \left(s, K_t, k_t^{(H)}\right)\right)
\times \left( D^{(H)}_{x_0 + t, t, 1}(s) + D^{(H)}_{x_0 + t, t, 3}(s) \left(K_t - \hat{K}_t\right) + D^{(H)}_{x_0 + t, t, 5}(s) \left(k_t^{(H)} - \hat{k}_t^{(H)}\right) \right),
$$

where $\phi$ represents the probability density function for a standard normal random variable.

The partial derivative of $Q_t(t_0)$ with respect to $K_t$ depends on the value of $t$ relative to the q-forward’s maturity date $t_0 + T^*$. If $t = t_0 + T^* - 1$:

$$
\frac{\partial Q_t(t_0)}{\partial K_t} = (1 + r)^{-1} \frac{\partial \Phi^{(R)}_{x_0, t} \left(1, K_t, k_t^{(R)}\right)}{\partial K_t}
$$

$$
= (1 + r)^{-1} \frac{\partial \Phi^{(R)}_{x_0, t} \left(1, K_t, k_t^{(R)}\right)}{\partial K_t}
$$

$$
\approx (1 + r)^{-1} \phi^2 \left(f^{(R)}_{x_0, t} \left(1, K_t, k_t^{(R)}\right)\right)
\times \left( D^{(R)}_{y, t, 1}(1) + D^{(R)}_{y, t, 3}(1) \left(K_t - \hat{K}_t\right) + D^{(R)}_{y, t, 5}(1) \left(k_t^{(R)} - \hat{k}_t^{(R)}\right) \right).
$$

If $t = t_0, \ldots, t_0 + T^* - 2$,

$$
\frac{\partial Q_t(t_0)}{\partial K_t} = (1 + r)^{-(t_0 + T^* - t)} \frac{\partial \Phi^{(R)}_{x_0 + t_0 + T^* - 1} \left(1, K_t, k_t^{(R)}\right)}{\partial K_t}
$$

$$
\approx (1 + r)^{-(t_0 + T^* - t)} \frac{\partial \left(-E(V_{t_0 + T^* - 1}^{(R)} | F_t)\right)}{\partial K_t}
\times \left( \sqrt{\text{Var}(V_{t_0 + T^* - 1}^{(R)} | F_t)} \right)
$$

$$
= (1 + r)^{-(t_0 + T^* - t)} \phi^2 \left( \frac{-E(V_{t_0 + T^* - 1}^{(R)} | F_t)}{\sqrt{\text{Var}(V_{t_0 + T^* - 1}^{(R)} | F_t)}} \right)
\times \left( \frac{-D_{y, t_0 + T^* - 1, 1}(1)}{\sqrt{\text{Var}(V_{t_0 + T^* - 1}^{(R)} | F_t)} \right).
$$

\[4\text{In the rest of this article, it is assumed that each q-forward used is closed 1 year after the launch date } t_0. \text{ Therefore, the actual calculations involve only the approximation formula for } t = t_0, t_0 + 1. \text{ The approximation formula for } t = t_0 + T^* - 1 \text{ is provided just for completeness.}\]
Evaluating the Hedge

As previously mentioned, \( N \) mortality scenarios are simulated to evaluate the effectiveness of the dynamic hedge.

Define by \( PL_t \) the time-0 value of all pension liabilities, given the information up to and including time \( t \); that is,

\[
PL_t = E \left( \sum_{s=1}^{\infty} (1 + r)^{-s} S_{x_0,0}(s) \mid F_t \right)
\]

\[
= \begin{cases} 
FL_0, & t = 0 \\
\sum_{s=1}^{t} (1 + r)^{-s} S_{x_0,0}(s) + (1 + r)^{-t} S_{x_0,0}(t) FL_t, & t > 0.
\end{cases}
\]

The value of \( PL_0 \) is nonrandom, as it is simply a function of \( K_0 \) and \( k_0^{(H)} \) whose values are fixed. For \( t > 0 \), the values of \( PL_t \) are different under different simulated mortality scenarios. In particular, the values of \( S_{x_0,0}(s) \) for \( s = 1, \ldots, t \) depend on the realized values of \( K_s \) and \( k_s^{(H)} \) for \( s = 1, \ldots, t \), whereas the value of \( FL_t \) depends on the realized values of \( K_t \) and \( k_t^{(H)} \).

It is assumed that at each time point \( t \), the hedger writes a new q-forward contract (i.e., a q-forward with inception date \( t_0 = t \)) with a notional amount of \( h_t \). The value of this position is \( h_t Q_t(t) = 0 \) at time \( t \) and becomes

\[
h_t Q_{t+1}(t) = h_t (1 + r)^{-(T^{*} - 1)} \left( q^{f} - E \left( q^{(R)}_{x_f,t+T^{*}} \mid F_{t+1} \right) \right)
\]

\[
= h_t (1 + r)^{-(T^{*} - 1)} \left( E \left( q^{(R)}_{x_f,t+T^{*}} \mid F_{t} \right) - E \left( q^{(R)}_{x_f,t+T^{*}} \mid F_{t+1} \right) \right)
\]

\[
= h_t (1 + r)^{-(T^{*} - 1)} \left( p^{(R)}_{x_f,t+T^{*} - 1} \left( 1, K_{t+1}, k_{t+1}^{(R)} \right) - p^{(R)}_{x_f,t+T^{*} - 1} \left( 1, K_t, k_t^{(R)} \right) \right)
\]

at time \( t + 1. \) At time \( t + 1 \), the position written at time \( t \) is closed out, and another new q-forward contract is written. The process repeats until the end of the hedging horizon \( Y \) is reached. For simplicity, we assume that all q-forwards used over the hedging horizon have the same maturity \( T^* \) and reference age \( x_f \).

Let \( PA_t \) be the time 0 value of the assets backing the pension plan at time \( t \). We assume that \( PA_0 = PL_0 \). For \( t = 1, \ldots, Y \), we have

\[
PA_t = PA_{t-1} + (1 + r)^{-t} h_{t-1} Q_t(t - 1).
\]

If \( PA_t \) is very close to \( PL_t \) for \( t = 1, \ldots, Y \), then the dynamic hedge can be said as successful. The potential deviation between \( PA_t \) and \( PL_t \) is the residual risk that is not mitigated by the hedge. Using this reasoning, we measure hedge effectiveness by the

---

\(^5\)The second step is due to our pricing assumption.
following metric:

\[ HE_t = 1 - \frac{\text{Var}(PA_t - PL_t|F_0)}{\text{Var}(PL_t|F_0)}. \]

A value of \( HE_t \) that is close to one indicates the hedge is effective.

**Analyzing the Dynamic Longevity Hedge**

**Assumptions**

The following assumptions are used in the baseline calculations.

1. The hedger wishes to hedge the pension liabilities that are payable to a single cohort of individuals, who are all aged \( x_0 = 60 \) at time 0. The mortality experience of these individuals is identical to that of the UK male insured lives.
2. The pension plan pays each individual $1 at the end of each year until death or age 90, whichever the earliest.\(^6\)
3. The hedging horizon is \( Y = 30 \) years (i.e., the hedge stops when the liabilities have completely run off).
4. The q-forwards used are linked to the England and Wales (EW) male population. They all have a time to maturity (from inception) of \( T^* = 10 \) years and a reference age of \( x_f = 75 \).
5. The market for the q-forwards is liquid and no transaction cost is required.
6. The interest rate for all durations is \( r = 4\% \) per annum. The interest rate remains constant over time.
7. The hedger can invest or borrow at an interest rate of \( r = 4\% \) per annum.
8. The values of \( D^{(i)}_{x,t,j}(T) \) for \( i = H, R \) and \( j = 0, \ldots, 5 \) are computed from an ACF model that is estimated to the data from the populations of EW males and UK male insured lives over the period of 1966–2005 and the age range of 60–89.\(^7\)
9. To match the end point of the data sample period, time 0 is set to the end of year 2005.
10. The evaluation of hedge effectiveness is based on \( N = 10,000 \) mortality scenarios that are generated from the model described in Assumption (8).
11. There is no small sample risk.

**Baseline Results**

The gray (larger) fan chart in the left panel of Figure 1 depicts the distributions of \( (PL_t - PL_0)|F_0 \) (or equivalently \( PL_t|F_0 \)) for \( t = 0, \ldots, 30 \) under the baseline assumptions. When there is no longevity hedge, the time 0 value of the assets backing the pension

---

\(^6\)We assume that no pension is payable beyond age 90, because the upper limit of the age range to which the ACF model is fitted is 89. This assumption may be relaxed if one assumes a parametric curve to extrapolate death probabilities beyond age 89.

\(^7\)The data for EW males are provided by the Human Mortality Database (2014), while the data for UK male insured lives are obtained from the Institute and Faculty of Actuaries by written request.
plan is always $FL_0$, because we assume $PA_0 = PL_0 = FL_0$. Hence, $PL_t - PL_0$ can be regarded as the shortfall in assets in the absence of a longevity hedge.

The green (smaller) fan chart in the left panel Figure 1 shows the distributions of $(PL_t - PA_t)|F_0$ for $t = 0, \ldots, 30$ under the baseline assumptions. We can regard $PL_t - PA_t$ as the shortfall in assets when a dynamic longevity hedge is in place. Over the entire hedging horizon, $(PL_t - PA_t)|F_0$ is significantly less dispersed than $(PL_t - PL_0)|F_0$, indicating that the longevity hedge is effective. Over the hedging horizon, the value of $HE_t$ is consistently larger than 90 percent.

To assess the extent of population basis risk, we repeat the calculations by assuming, hypothetically, that q-forwards linked to the population of UK male insured lives are available and used. The hedging results are shown in the right panel of Figure 1. The degree of population basis risk can be observed from the difference in the widths of the green fan charts in left and right panels of Figure 1.

Robustness

We have tested the robustness of the dynamic hedging strategy relative to various factors. The tests performed are detailed in Online Appendix D. The conclusions drawn from the tests are summarized below.

- When the simulation model contains two stochastic factors, the hedging result is not as good as the baseline result; however, the value of $HE_{30}$ is still above 90 percent.
• In line with the results produced by Li and Hardy (2011), the impact of small sample risk is modest \(HE_{30} = 86.19\%\) when the initial number of pensioners is 10,000.
• Regardless of which simulation model is used, the hedge effectiveness remains high if the q-forward’s reference age \(x_f\) is in between 70 and 80.
• The relationship between hedge effectiveness and the q-forward’s time to maturity \(T^*\) depends on the simulation model. For all simulation models considered, the hedging results are still satisfactory even if the time to maturity is as short as 5 years.

MANAGING THE RESIDUAL RISKS
In this section, we explain how the residual risks from a dynamic, index-based longevity hedge can be managed through a reinsurance mechanism.

Assumptions
As we expand our analysis to include more than two populations, some of the previously made assumptions have to be modified accordingly. Below we list the assumptions that are used in this section.

(i) There are 25 pension plans wishing to hedge their longevity risk exposures. The 25 pension plans have, respectively, identical mortality experience to 25 different male populations. The chosen populations are the same as the 25 populations that are classified as the “males West-cluster” by Hatzopoulos and Haberman (2013).
(ii) Each pension plan contains initially \(l_{60} = 3,000\) pensioners who are all aged \(x_0 = 60\). For \(x = 61, 62, \ldots, l_x\) follows the binomial process described in the “Robustness Relative to Small Sample Risk” section in Online Appendix D.
(iii) At any time point during the hedging horizon, the only hedging instrument available is a q-forward that is linked to EW male population with a time-to-maturity (from inception) of \(T^* = 10\) years and a reference age of \(x_f = 75\).
(iv) The values of \(D_{x,t}^{(i)}(T)\) for \(i = 1, \ldots, 25\) and \(j = 0, \ldots, 5\) are computed from an ACF model that is estimated to the data from the 25 male populations under consideration.\(^8\)
(v) To match the end point of the data sample period, time 0 is set to the end of year 2009.
(vi) The evaluation of hedge effectiveness is based on \(N = 10,000\) mortality scenarios that are generated from the model described in Assumption (iv).

Assumptions 2, 3, 5, 6, and 7 stated in the “Analyzing the Dynamic Longevity Hedge” section remain unchanged.

Customized Surplus Swaps
A dynamic longevity hedge is implemented for each of the 25 pension plans. The hedging results are reported and discussed in Online Appendix E.

\(^8\)The mortality data for all 25 male populations are obtained from the Human Mortality Database (2014). The data used cover a sample period of 1959–2009 and a sample age range of 60–89.
The values of $HE_{30}$ range from 37 to 79 percent. The results indicate that the dynamic longevity hedge may leave substantial residual risks, which include small sample risk and population basis risk. We hereby propose a customized surplus swap that permits pooling of the residual risks from different dynamic longevity hedges. When implementing such a swap in tandem with a dynamic index-based hedge, the pension plan would in theory be immunized from longevity risk.

A pension plan is immunized from longevity risk over the hedging horizon if $PA_t - PL_t = 0$ for $t = 1, \ldots, Y$. We can regard $|PA_t - PL_t|$ as the pension plan’s surplus if $PA_t > PL_t$ and short fall in assets if $PA_t < PL_t$. The swap we design has a maturity of 1 year and is written at each time point when the dynamic index-based hedge is established or adjusted. We call it a “surplus” swap, because its net cash flow at maturity is derived from the surplus process $PA_t - PL_t$, $t = 1, \ldots, Y$, of the pension plan.

Our goal is to ensure that $PA_t - PL_t = 0$ for $t = 1, \ldots, Y$. We let $NCF_t$ be the net cash flow (payable at time $t$ from the reinsurer to the pension plan) for the customized surplus swap that is written at time $t - 1$. With the swap in place, the recursion formula for $PA_t$ can be rewritten as

$$PA_t = PA_{t-1} + (1 + r)^{-t}(h_{t-1}Q_t(t - 1) + NCF_t), \quad t = 1, \ldots, Y,$$

(3)

where $PA_0 = PL_0$. Using Equations (2) and (2), we obtain

$$PL_t - PA_t = PL_{t-1} - PA_{t-1} + (1 + r)^{-t}(S^{(H)}_{x_{0,0}}(t)(1 + FL_t) - (1 + r)S^{(H)}_{x_{0,0}}(t - 1)FL_{t-1})$$

$$- (1 + r)^{-t}(h_{t-1}Q_t(t - 1) + NCF_t), \quad t = 1, \ldots, Y.$$

To stipulate $PA_t - PL_t = 0$ for $t = 1, \ldots, Y$, we require

$$NCF_t = S^{(H)}_{x_{0,0}}(t)(1 + FL_t) - h_{t-1}Q_t(t - 1) - (1 + r)S^{(H)}_{x_{0,0}}(t - 1)FL_{t-1}, \quad t = 1, \ldots, Y.$$

The expression for $NCF_t$ is intuitive. It says that there is no net cash flow from the swap if what the pension plan has at time $t - 1$ accumulated with interest (i.e., $(1 + r)S^{(H)}_{x_{0,0}}(t - 1)FL_{t-1}$) plus the proceed from the index-based hedge at time $t$ (i.e., $h_{t-1}Q_t(t - 1)$) is just sufficient to cover the plan’s financial obligations at time $t$ (i.e., $S^{(H)}_{x_{0,0}}(t)$) and beyond (i.e., $S^{(H)}_{x_{0,0}}(t)FL_t$).

Given $F_{t-1}$, the value of $(1 + r)S^{(H)}_{x_{0,0}}(t - 1)FL_{t-1}$ is known, but the values of $S^{(H)}_{x_{0,0}}(t)(1 + FL_t)$ and $h_{t-1}Q_t(t - 1)$ are random as they both depend on the values of $K_t$, $k_t^{(H)}$, and $k_t^{(R)}$, which are not known until time $t$. It follows that for a customized surplus swap written at time $t - 1$, the fixed and floating legs should be set to $(1 + r)S^{(H)}_{x_{0,0}}(t - 1)FL_{t-1}$ and $S^{(H)}_{x_{0,0}}(t)(1 + FL_t) - h_{t-1}Q_t(t - 1)$, respectively.
Given how the cash flows are defined, the following should be incorporated into the terms of a customized surplus swap written at time $t - 1$:

- the method and assumptions used to calculate $FL_{t-1}$ and $FL_t$;
- the hedge ratio $h_{t-1}$;
- the rate $r$ at which the cash flows are discounted;
- the forward mortality rate $q^f$ associated with the q-forward written at time $t - 1$.

For simplicity, we assume that the swap is costless in the following illustration. In practice, of course, the reinsurer demands a reward for taking on the risk, and therefore, a fixed payment (the risk premium) has to be paid by the pension plan to the reinsurer at either inception or maturity.

An Illustration

We now revisit the index-based longevity hedges for the 25 pension plans. Let us suppose that on top of the index-based hedges, all 25 pension plans write customized surplus swaps with the same reinsurer to eliminate their exposures to the residual risks. Assume further that the assumptions used in formulating the index-based hedges also apply to the terms of the customized surplus swaps.

The fan charts in Figure 2 show the distributions of $NCF_t | \mathcal{F}_0$ for the 25 pension plans. Several comments on the fan charts are made in Online Appendix F.

To study the diversifiability of the residual risks from the index-based hedges, let us consider the cash flows from the viewpoint of the reinsurer who writes customized surplus swaps with the 25 pension plans. The fan chart in the left panel of Figure 3 depicts the distributions (conditioned on $\mathcal{F}_0$) of the average net cash flows payable to each pension plan over the hedging horizon. The variability of the reinsurer’s average net cash flows is small compared to the variability of $NCF_t$ for individual pension plans. The diversifiability can be observed more clearly from the right panel of Figure 3, which compares the variances of the reinsurer’s average net cash flows with the variances of the net cash flows arising from individual customized surplus swaps.

Discussion and Conclusion

In this article, we consider a risk management framework in which longevity risk is split into trend risk and residual risks. With the proposed dynamic hedging strategy, a pension plan can transfer its trend risk exposure to capital markets through standardized instruments. Using the proposed customized surplus swap, the pension plan may also transfer the residual risks left behind by the dynamic hedge to a reinsurer, who collectively manages the residual risks from various pension plans. As a whole, our risk management framework allows pension plans to completely eliminate their longevity risk exposures, just as what they can achieve from traditional, entirely insurance-based pension derisking solutions.

What we propose allows the longevity risk transfer market to package the trend risk as standardized products that are structured like typical capital market derivatives.
Compared to products such as pension buy-ins, standardized mortality derivatives are more appealing to capital market investors who generally desire liquidity and transparency. When put in practice, our risk management framework may attract participation from capital markets, thereby ameliorating the demand and supply imbalance in the present market for longevity risk transfers. The enhancement of liquidity through standardization may also result in lower risk management costs to pension plans, as the illiquidity premium payable to the counterparty can be reduced. Although there are no sufficient data to test the inverse relationship between liquidity and compensation to investors (typically measured by the Sharpe ratio) in the longevity risk market, there is profound evidence for such an inverse relationship in several financial markets.

For stock markets, the inverse relationship between liquidity and risk-adjusted rate of return is identified by Lo, Petrov, and Wierzbicki (2003), who introduce liquidity to the standard mean-variance portfolio optimization framework by constructing three-dimensional mean-variance-liquidity frontiers on the basis of several measures of liquidity including trading volume and percentage bid/offer spreads. They study the tangency portfolios of the liquidity-constrained mean-variance-liquidity efficient
Figure 3
An Illustration of the Diversifiability of the Residual Risks From the Index-Based Hedges

Note: The left panel shows the distributions (conditioned on $\mathcal{F}_0$) of the average net cash flows payable from the reinsurer to each pension plan over the hedging horizon. The right panel shows the values of $\text{Var}(NCF_t|\mathcal{F}_0)$, $t = 1, \ldots, 30$, for the individual customized surplus swaps (the dotted lines) and the corresponding variances of the reinsurer’s average net cash flows payable to each pension plan (the solid line).

frontiers for some randomly selected stocks, and find that the Sharpe ratio of the tangency portfolio reduces as the liquidity threshold becomes less stringent.

For mutual fund markets, the relationship between liquidity and risk-adjusted rate of return is revealed by Idzorek, Xiong, and Ibbotson (2012), who investigate whether mutual funds that hold less liquid stocks tend to outperform those that hold more liquid stocks. They first group the population of mutual funds under consideration by size and valuation, and then categorize the funds in each group into five liquidity levels on the basis of the stock-level “turnover” measure. They find that, on average, mutual funds that held less liquid stocks possessed higher Sharpe ratios than those that held more liquid stocks.

For hedge fund markets, Getmansky, Lo, and Makarov (2004) study the potential relationship between liquidity and returns on hedge funds by developing an econometric model from which smoothing-adjusted Sharpe ratios were calculated. They find that among 908 hedge funds from the TASS Hedge Fund Combined databases, the most illiquid hedge funds (e.g., fixed income directional) had the highest smoothing-adjusted Sharpe ratios, supporting the inverse relationship between liquidity and risk-adjusted required rate of return.

It has been argued that the market for longevity risk transfers has many similarities compared to a typical financial market (Loeys, Panigirtzoglou, and Ribeiro, 2007).
Hence, it is reasonable to conjecture that the inverse relationship between liquidity and Sharpe ratio found in stock, mutual fund, and hedge fund markets also applies to the market for longevity risk transfers. If this conjecture holds, then our risk management framework would be more economical than the comparable entirely insurance-based methods, because it could transfer the trend risk at a lower cost. A reduced cost may encourage more pension plans to transfer their longevity risk exposures, thereby not only facilitating market growth but also strengthening the stability of the pension industry.

To focus on the design and execution of the proposed risk management methods, we make no attempt to estimate the associated costs. It thus warrants a separate study to investigate how much the proposed risk management methods may cost. To determine the cost associated with the dynamic longevity hedge, one may replace \( q_f \) with a forward mortality rate that is derived from the pricing methods proposed by Chuang and Brockett (2014), Li, Ng, and Chan (2011), Deng, Brockett, and MacMinn (2012) and Li and Hardy (2011). As a reinsurance treaty, the customized surplus swap may be priced under the Solvency II framework. In particular, its profit margin may be calculated by multiplying the present value of the solvency capital requirements with the spread over risk-free rate that the reinsurer is required to earn on its equity (see Zhou et al., 2014). Also, to understand the value for money of our risk management framework, it would be interesting to compare the total cost required by the proposed risk management methods with that required by a full pension buy-out.

As the proposed dynamic hedging strategy matches only the first partial derivatives (with respect to the only common stochastic factor \( K_t \) in the ACF model), it requires the hedger to hold only one hedging instrument at a time. This property may be seen as advantageous, because it helps the market to concentrate liquidity. In future research, one may extend the proposed dynamic hedging strategy to match also the higher order derivatives, and to investigate whether such an extension would lead to an improvement in hedge effectiveness that worths the dilution of liquidity arising from the use of additional instruments.

We acknowledge that the proposed hedging strategy takes no account of the correlation between \( \frac{\partial}{\partial t} L_t(x) \) and \( \frac{\partial}{\partial t} S_t(x) \). Thus, it may not have fully unleashed the potential of a dynamic index-based longevity hedge. Because both \( F_t \) and \( Q_t(t_0) \) are not functions of \( \text{corr}(\frac{\partial}{\partial t} L_t(x), \frac{\partial}{\partial t} S_t(x)) \), it is not trivial to incorporate \( \text{corr}(\frac{\partial}{\partial t} L_t(x), \frac{\partial}{\partial t} S_t(x)) \) into traditional Greek hedging methods that are based on the partial derivatives of \( F_t \) and \( Q_t(t_0) \). However, we may possibly incorporate the correlation between \( \frac{\partial}{\partial t} L_t(x) \) and \( \frac{\partial}{\partial t} S_t(x) \) by considering the generalized state-space hedging method (Liu and Li, 2014, 2015), in which the optimal hedging strategy depends on the correlation matrix of the random innovations in the processes for the hidden states (i.e., the time-varying stochastic factors). This extension is left for future research.

The results of various robustness tests indicate that the effectiveness of the dynamic longevity hedge is reasonably robust relative to model risk and the parameters of the q-forwards used. They also offer some useful insights to market participants. For

---

\(^9\)Mercer provides pension buy-out indexes, which track the estimated cost of a full pension buy-out in the United States, the United Kingdom, Ireland, and Canada over time.
example, because the dynamic hedge still yields satisfactory hedging results even if the time to maturity of the q-forwards is only 5 years, the market may choose to launch shorter-dated q-forwards, which are more likely to attract capital market investors. As robustness is important in gaining trust from various stakeholders, we believe that future research warrants a more extensive analysis of robustness that considers additional aspects of the longevity hedge (e.g., hedge ratios) and additional factors that may affect hedge effectiveness (e.g., parameter risk).

In illustrating the customized surplus swap, mortality data from a group of distinct national populations are used. In reality, however, a reinsurer may possibly write customized surplus swaps with pension plans that are located in the same country, so it is also important to understand the diversifiability of residual risks across subpopulations with the similar geographical locations but different social-economic statuses. Such an understanding may be developed by considering the Club Vita data set of UK occupational pension schemes used by Haberman et al. (2014). We suggest revisiting the study of the customized surplus swap when the Club Vita data set becomes available from the public domain.
