(Dated: 2 August 2019)

This paper investigates the processes by which stable boundary layers are formed through strong surface cooling imposed on neutrally stratified wall-bounded turbulence using high-resolution direct numerical simulation at a moderate Reynolds number. The adjustment of the flow to the imposed strong surface cooling is investigated. We further focus on a strongly stable case where turbulence partially collapses. We show that, due to significant reduction in turbulence production, turbulence becomes patchy, with a band of turbulence coexisting with quiet regions. The nature of the quiet regions, which are often characterized as laminar, is investigated and shown to be consistent with viscously coupled stratified turbulence. The one-dimensional longitudinal streamwise velocity spectrum exhibits $k^{-5}$ and $k^{-3}$ behavior in the buffer and logarithmic layer, respectively, adjacent to an active region of three-dimensional turbulence with a $k^{-5/3}$ spectrum. Scenarios for turbulence recovery from such a patchy state are also discussed. We show that the presence of outer layer turbulence above $z^+ \approx 300$ is a key requirement for recovery. For higher values of stratification, it is shown that inner layer turbulence is damped entirely and outer layer turbulence is damped subsequently.

I. INTRODUCTION

Turbulence plays a central role in the dynamics of the atmospheric boundary layer (ABL), e.g. in the mixing of heat and water vapor, dispersion of air pollutants, and cloud formation. However, stable stratification, in which heavier air lies under lighter air, significantly affects boundary layer turbulence.1–4 Strongly stable stratification may lead to co-existence of turbulence and internal waves, infra-red intermittency, or oblique laminar-turbulent patterns.5 These features of the strongly stable regime demand extra consideration and add additional challenges for numerical simulations (e.g. stratospheric collapse of turbulence).4 Because of the complexity of the stably stratified regime, it presents a challenge for parameterization of boundary layer mixing in weather forecasting models.

The stably stratified boundary layer (SBL) can form by radiative cooling of the surface (e.g. nocturnal ABL) or by advection of warm air over cold surfaces (e.g. ABL over sea ice). From an environmental perspective, the SBL can lead to a decrease in the dispersion of air pollutants or an accumulation of aerosols (e.g. black carbon) in near-surface regions.9,10,11 The SBL can also adversely impact the local ecology by rapid depletion of nutrients due to the decrease in surface layer mixing.12,13 From the perspective of wind energy, stable stratification can cause a significant reduction in the total power output of large wind farms.14

In the SBL, the dynamics of turbulence and the energy cascade are controlled by the simultaneous effects of stable stratification and the solid boundary. For stable stratification, energy is transferred from large anisotropic eddies to smaller and more isotropic eddies. In

a) atoufi@uwaterloo.ca
particular, for scales above the Ozmidov scale, anisotropy is characterized by thin pancake vortices, layers of strong shear, and gravity waves; below the Ozmidov scale, there is a transition to more isotropic three-dimensional turbulence\textsuperscript{15–17}. The presence of the wall, on the other hand, creates another source of anisotropy by which the size of the energy-containing eddies increases when moving away from the wall. This causes an inverse spatial cascade in the near-wall region where energy and momentum are transferred from smaller eddies to larger eddies aloft\textsuperscript{18,19}.

The SBL has been the subject of numerous studies by numerical simulations and atmospheric measurements and observations\textsuperscript{3}. However, the interplay of the solid boundary and stratified turbulence, particularly for strong stratification, has been less studied\textsuperscript{4}. Some of the outcomes of these studies of stably stratified wall-bounded turbulence (mostly from numerical simulations of closed or open channel flow) are briefly reviewed here.

SBL flows can be classified into “buoyancy affected”, “buoyancy controlled”, or “buoyancy dominated” based on Richardson and Reynolds number\textsuperscript{20}. SBL turbulence is sustained for weak stratification or high Reynolds number (buoyancy affected flows)\textsuperscript{21–23}. Nevertheless, stratification substantially affects turbulence in the outer layer while the near-wall region and the logarithmic layer remain almost unaffected\textsuperscript{21,25}. For moderate stratification (buoyancy controlled flows), symmetry around the center of the closed channel is broken\textsuperscript{20}. However, symmetry is eventually restored through a transition process by eddies crossing over the channel center\textsuperscript{20}. Open channel flows at moderate stratification have lower turbulent mass flux, lower density gradient, and higher values for the ratio of potential energy to vertical turbulent kinetic energy\textsuperscript{21} compared to the weak stratification regime.

For strong stratification or low Reynolds number (buoyancy dominated flows), the turbulence production mechanism is significantly suppressed by stratification, leading to decoupling of the inner and outer layers\textsuperscript{20} or formation of large laminar patches in the near-wall region\textsuperscript{7,8,23,24} (depending on stratification level) where strongly stable stratification damps the intensity of near-wall streaks\textsuperscript{5,23} generated from global modes\textsuperscript{23}. The damping of these modes eventually leads to vanishing of turbulent momentum and buoyancy fluxes in the core of the channel due to the disappearance of large-scale streaks in near-wall region\textsuperscript{23}. The dominance of internal gravity waves in the central region has also been observed for buoyancy dominated flows in closed channel simulations\textsuperscript{5,6,23}.

Although flow characteristics are fundamentally different for each of these three stratification regimes, they have some common basic features. For example, increasing stratification leads to an increase in the mean streamwise velocity, decrease in the skin friction coefficient, decrease in vertical velocity fluctuations, and decrease in tangential Reynolds stress\textsuperscript{5,7,21–25}.

In the buoyancy dominated SBL, the ratio of the Monin-Obhukov (MO) length to the channel height is often used to indicate whether turbulence will survive or collapse\textsuperscript{7,22}. The MO scale $L_{MO}$ is defined as\textsuperscript{7}

$$
\frac{L_{MO}}{h} = -\frac{u^3_+ / \left( \kappa h \right)}{(g/\theta) \hat{\theta w}}.
$$

where $u_+$ is the friction velocity based on the wall shear stress, $\kappa \approx 0.41$ is the von Kármán constant, $h$ is a reference length scale (channel height for open channel flow configuration and channel half height for closed channel), and $\hat{\theta w}$ is the vertical temperature flux at the bottom surface, where the overbar denotes a horizontal average. Essentially, $L_{MO}$ is the height at which the temperature flux at the bottom surface is of the same order as the turbulent energy production in the log-law region, where stratification effects are assumed to be small\textsuperscript{7}.

Nieuwstadt\textsuperscript{22} performed pioneering direct numerical simulations (DNS) of a turbulent open channel flow with a uniformly cooled bottom surface and fixed-temperature upper surface and introduced $h / L_{MO}$ as a stability parameter. He reported that turbulence survives only for $h / L_{MO} < 1.25$, for which most locations in the channel satisfy $Ri^b_2 < 0.25$, where the gra-
The gradient Richardson number $Ri_g = N^2/S^2$ is the squared ratio between the buoyancy frequency $N$ and mean shear $S$ averaged over horizontal planes. He showed that turbulence decays for larger values of $h/L_{MO}$. Similar criteria have been found for turbulence collapse at higher Reynolds numbers and larger computational domain sizes.

Flores and Riley performed DNS of a case similar to Nieuwstadt at higher Reynolds and Richardson numbers as an idealized model for the nocturnal atmospheric surface layer. They found that surface cooling causes the turbulence statistics near the ground to adjust on a time scale on the order of $L_{MO}/u_\tau$. They found that turbulence is sustained for relatively weak cooling, but when the Monin-Obukhov Reynolds number $Re_{L_{MO}} = L_{MO}u_\tau/\nu$ falls below around 100, turbulence collapses. Here $\nu$ is the kinematic viscosity. This criterion implies that the logarithmic layer is not large enough to accommodate a buffer region beneath when $Re_{L_{MO}} \lesssim 100$ since the height of buffer region is about $100\nu/u_\tau$. A similar study related turbulence collapse as a local process, regardless of the outer region dynamics. To reach that conclusion, they simulated a capped Ekman layer, which has a different outer flow and found similar criteria.

Donda et al. also performed DNS of an open channel flow with setup similar to the work of Nieuwstadt, and showed that recovery of turbulence would occur if perturbations of finite amplitude are imposed on the laminarized state after sufficient time. They argued that in the SBL, the available momentum in the bulk of the flow limits the downward heat flux to a maximum, which they called the maximum sustainable heat flux (MSHF). This limit is due to the fact that the time scale of boundary layer diffusion is much smaller than the time scale for flow acceleration and therefore the available momentum for downward heat transport is limited in the case of strong surface cooling. For surface cooling rates larger than MSHF, efficient vertical heat transport hinders and eventually causes turbulence to be suppressed fully by the intensive density stratification.

The focus of these previous studies has been the stationary SBL when turbulence is strong enough to survive surface cooling, and/or the determination of conditions for turbulence collapse. Another question that has been less discussed in the literature is how a neutrally stratified boundary layer transforms to a SBL through surface cooling. This question is of particular relevance to the formation of a nocturnal ABL. Answering this question can improve our understanding of 1) the process under which turbulence collapses for strongly stable stratification, and 2) the mechanism by which turbulence may or may not recover from such collapse. Addressing these questions is the central focus of this paper.

In this paper, we aim to study how a neutral boundary layer evolves into a SBL in the presence of surface cooling. In particular, we investigate how wall turbulence responds to strong surface cooling, how patchiness appears through adjustment of wall turbulence to strong stratification, and how turbulence may recover from such patchy states. This paper starts with a general statement of the problem in Sec. II where the mathematical formulation, governing equations, dimensionless parameters, and boundary conditions are introduced. The computational approach, simulation parameters, and properties of the database generated in this investigation are discussed in Sec. III. In Sec. IV, simulation results are presented. First, we describe the feedback process over which the flow responds to strong surface cooling. Then possible feedback mechanisms that may be responsible for flow adjustment are considered. The paper ends with concluding remarks in Sec. V.
and outline the different layers of the stratified boundary layer.

A. Test case description

The motivation for the present work is to study turbulence in the surface layer of a stably stratified dry ABL. To do so, an open channel flow configuration is considered, with an imposed cooling flux at the lower boundary and an adiabatic upper boundary. The geometry of the open channel is shown in Fig. 1. A uniform pressure gradient drives flow in the $x$ direction, periodic boundary conditions are applied in both horizontal directions, while no-slip and no-stress surfaces are applied to the bottom and top boundaries, respectively. The $y$ axis is the cross-stream direction and the $z$ axis is normal to the wall. The velocities in the $x$, $y$, and $z$ directions are denoted by $u$, $v$, and $w$, and we let $(x_1, x_2, x_3) = (x, y, z)$ and $(u_1, u_2, u_3) = (u, v, w)$. The domain size in the $x$ and $y$ directions is $L_x$ and $L_y$, respectively and the channel depth is $h$. The temperature field is denoted by $\theta$ and is defined as the fluctuation from background $\theta_0$. For simplicity, the free surface is assumed to be undeformed, an approximation applicable for low Froude number $^{31-34}$ which is a common approach in studies of the idealized ABL $^7,22,35$.

B. Governing equations and dimensionless parameters

The governing equations for this work are the Navier-Stokes equations under Oberbeck-Bousinesq approximation (OBA). The OBA equations can be normalized using the channel height $h$, a reference velocity $u_0$, and the value of the imposed bottom-surface temperature gradient $F$. With these choices, the dimensionless OBA equations can be written as $^{21,24}$

$$\frac{\partial u_i}{\partial x_i} = 0, \quad (2)$$

$$\frac{\partial u_i}{\partial t} + u_j \frac{\partial u_i}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{1}{Re} \frac{\partial^2 u_i}{\partial x_j \partial x_j} + \frac{Re Ri}{\theta^2} \frac{\partial \theta}{\partial x_3} + \delta_{i3}, \quad (3)$$

$$\frac{\partial \theta}{\partial t} + u_j \frac{\partial \theta}{\partial x_j} = \frac{1}{Pr Re} \frac{\partial^2 \theta}{\partial x_3 \partial x_3}, \quad (4)$$

where $Re$, $Ri$, and $Pr$ are reference Reynolds, Richardson and Prandtl numbers. Here we assume constant background (reference) temperature $\theta_0$ in hydrostatic balance with background pressure. The variable $p$ is the pressure fluctuation from the background pressure. Density and temperature are related through the linearized equation of state for an ideal gas $^2$. In practice, we use unit reference values $u_0 = 1$, $h = 1$, and $F = 1$, so $u_i$ and $\theta$ can be interpreted as dimensional variables.

Wall scale non-dimensional parameters are defined as

$$Re_\tau = \frac{u_\tau h}{\nu}, \quad Ri_\tau = \frac{g}{\theta_0} \frac{F h^2}{u_\tau^2}, \quad (5)$$

where friction velocity $u_\tau = (\tau_w/\rho_0)^{1/2}$, $\rho_0$ is the reference density, and $g$ is the gravitational acceleration. Here $\tau_w$ is the surface shear stress. The imposed uniform horizontal pressure gradient drives flow in the $x$ direction and forces the mean flow to balance the mean wall shear stress (averaged over the horizontal plane) and maintain the flow from deceleration in the streamwise direction. Thus, the time dependant val-
ues of $Ri_\tau$ and $Re_\tau$ will converge to their corresponding reference values $Ri$ and $Re$ as the flow approaches stationarity.

The bulk Richardson and Reynolds numbers are defined by

$$Re_b = \frac{U_b h}{\nu}, \quad Ri_b = \frac{g \theta_0 F h^2}{U_b^2},$$

(6)

where $U_b = \frac{1}{\pi} \int \pi \, dz$ is the bulk velocity, and $\langle \cdot \rangle$ denotes averaging over horizontal planes at each $z$. Note that because the vertical gradient of temperature is specified at the lower surface, $Ri_\tau$ is the parameter that determines cooling rate, and therefore stratification regime. Bulk and friction Richardson number are related through $Ri_b = Ri_\tau u_\tau^2 / U_b^2$.

The boundary conditions are:

$$z = 0 : \quad u = v = w = 0, \quad \frac{\partial \theta}{\partial z} = 1,$$

(7)

$$z = h : \quad \frac{\partial u}{\partial z} = \frac{\partial v}{\partial z} = w = \frac{\partial \theta}{\partial z} = 0.$$

(8)

This choice of no heat flux at the upper boundary excludes heat entrainment from above and provides a framework to focus on the effect of surface cooling alone on wall generated turbulence. Although this choice leads to a constant rate of change in mean temperature\(^2\), it will be shown that the mean velocity, mean temperature gradient, and fluctuating quantities reach equilibrium after sufficient time.

Two dimensionless scaling quantities, which are called wall units and frequently used in the analysis of wall-bounded flows, are defined as\(^3\): \(^6\),\(^7\):

$$z^+ = \frac{zu_\tau}{\nu}, \quad u^+ = \frac{u}{u_\tau}.$$

(9)

Throughout the paper, superscript $^+$ denotes non-dimensionalization by near wall scaling parameters $(u_\tau^2, \nu)$ (e.g. $z^+ = z u_\tau^2 / \nu$) and superscript $^o$ represents non-dimensionalization by outer layer scaling parameters $(u_\tau^o, h)$ (e.g. $t^o = tu_\tau^o / h$) where the $u_\tau^o$ refers to the initial value of the friction velocity (i.e. friction velocity of neutral case).

It is well-known that different layers exist in neutrally-stratified wall turbulence. These layers are classified as the viscous sublayer, buffer layer, logarithmic layer, and outer layer\(^37\)–\(^39\). With wall unit parameters, one can obtain universal profiles for mean velocity at a certain distance from the wall regardless of the details of the boundary layer\(^39\). Collectively, the viscous sublayer, buffer layer, and logarithmic layer are referred to as the inner layer in this study. The outer layer is the outer most part of the boundary layer where viscosity has an insignificant effect on the mean and turbulent quantities. In the outer layer, the boundary layer thickness $\delta$ or channel flow half height is the length scale of the eddies\(^37\).

### III. NUMERICAL APPROACH

The numerical model used for this study is Hercules, which is a scalable open-source DNS solver that solves the OBA equation for a channel flow configuration\(^24\). Minor modifications to include different type of surface temperature boundary conditions have been implemented in the code. Hercules has been validated for a wide range of Reynolds and Richardson numbers in a previous study\(^24\) for unstratified channel flow at $Re_\tau = 180, 395, 590$ and for a stratified channel flow at $Re_\tau = 180$ for Richardson numbers $Ri_\tau = 0, 18, 120, 480$.

The governing equations are discretized using the Fourier spectral method in the horizontal plane with periodic boundary conditions and a second-order central finite difference scheme in the vertical direction\(^25\). In horizontal directions we employ a uniform mesh, co-located variables and use the Fourier transform to calculate derivatives\(^40\). The two-thirds de-aliasing technique has been used to prevent aliasing error from energy transfer to unresolved wavenumbers\(^41\).

In the wall-normal direction, a second order finite-difference scheme is used and the nonlinear terms are treated in skew-symmetric form to reduce the amplitude of aliasing errors\(^42\) for
derivatives in the vertical direction. The mesh is Cartesian and non-uniform in the vertical direction. A vertically staggered grid is employed, in which the vertical velocity is located at cell faces and the horizontal velocity, pressure, and scalars are defined at cell centers. The staggering is done to remedy the problem of pressure-velocity decoupling and checkerboard oscillation of pressure\(^4\). Linear interpolation is used to map variables between the half-grid and full-grid points.\(^24,25\)

Hyperbolic tangent stretching is used in the \(z\)-direction to condense grid points near the solid boundaries to resolve the near-wall small-scale structures, with level \(i\) at\(^24,25\):

\[
z_i = h - \frac{h}{\tanh(2\alpha)} \tanh\left(\frac{2\alpha}{1 - N_z(i - N_z)}\right),
\]

(10)

where \(\alpha = 1.1\) is a parameter to control the stretching and \(N_z\) is the number of grid points in the vertical direction.

A. Overview of simulations

In this study, we considered one neutral and five stratified simulations with \(Ri\) up to 2800. A summary table of the simulations is presented in Table I. Case C1 refers to the neutral case in which temperature is a passive scalar and buoyancy frequency

\[
N^2(z) = \frac{g}{\theta_0} \frac{d\theta}{dz}
\]

(11)

is zero everywhere. Fields from the stationary state of the neutral case are used to initialize other simulations. The Prandtl number is set to unity in all cases.

Simulations are performed on a computational domain \(L_x/h = 2\pi\), \(L_y/h = \pi\) with resolution \(N_x \times N_y \times N_z = 768 \times 768 \times 384\) for a moderate Reynolds number \(Re = 560\) which correspond to wall unit grid spacings \(\Delta x^+ = 4.6\), \(\Delta y^+ = 2.3\), and \(\Delta z^+ \in [0.08 - 3.3]\). The domain size and physical parameters are comparable to the case S00-S12 in Flores and Riley\(^7\) but approximately three times higher spatial resolution in the horizontal directions and two times in the vertical direction is used to analyze small scale features of strongly stable wall turbulence. This resolution is comparable to the work of Vreman and Kuerten\(^4\) which used high resolution to study statistics of velocity derivatives. The time step is equal to \(\Delta t = 0.0002\) in C1 and C2 and \(\Delta t = 0.00015\) for the other cases. Fields are output with at interval \(t_s\), where \(t_s u_+ / h \approx [0.02 - 0.1]\). This output frequency corresponds to \(t_s \approx [1 - 8] t_\eta\) where \(t_\eta\) is Kolmogorov timescale\(^4\) obtained using minimum values of the domain averaged viscous dissipation throughout simulation time history.

Although the size of the computational domain considered here is small, it is large enough to contain the widest flow structure associated with at least one ejection and corresponding sweep, and therefore it allows maintenance of “healthy” turbulence in the sense of producing correct mean flow behavior and one-point statistics when compared to simulations with larger domains\(^4\). In addition, it has recently been shown that for channel flow simulations with passive heat transfer, this domain size accurately predicts the evolution of turbulent heat flux and RMS values of fluctuating temperature\(^4\).

IV. RESULTS

A. Overview

In this section, we first categorize the different phases of the wall turbulence response to surface cooling. Then, we further classify stratification regimes based on differences in the feedback process for different cooling rates. It will be shown that there is a critical cooling rate at which turbulence becomes patchy, and beyond which there is total suppression of turbulence. The mechanism for these feedback processes is also discussed.

Figure 2(a-d) shows time series of friction and bulk Reynolds and Richardson numbers. Figure 2(e-f) shows time series of domain integrated $k$ and $K$, where $k = u_i'u_i'/2$ is turbulent kinetic energy (TKE) and $K = u_iu_i'/2$ is mean kinetic energy (MKE). Prime denotes fluctuation from horizontal average. After stratification is introduced at $t^o = 0$, the friction velocity initially decreases, which leads to reduced wall shear stress. This reduction of shear stress with increasing stratification is consistent with field observations of stably stratified ABLs and laboratory experiments of SBLs. Consequently, the bulk velocity and bulk Reynolds number increase due to flow acceleration. The evolution of the friction Reynolds number exhibits three different phases: turbulence decay, turbulence recovery, and a quasi-stationary state. The evolution of domain integrated TKE also shows similar trend (Fig. 2f).

Turbulence decay starts from the introduction of stratification at $t^o = 0$ and lasts up to $t^o \approx 4 - 6$ in all cases, where TKE reaches its minimum through the cooling process. The recovery phase starts at the time associated with the TKE minimum. The duration of the recovery phase depends on $Ri$, where higher $Ri$ requires more time for recovery. For example, while for case C2 the recovery phase continues up to $t^o \approx 20$, for C5 it lasts until $t^o \approx 45$. This difference is consistent with the time scale of the flow adjustment $L_{MO}/u_r$ as suggested in Ref. 7. However, the recovery phase is different for the lower $Ri$ cases (C2 and C3) compared to the higher $Ri$ cases (C4, C5). In the former cases recovery involves a monotonic increase in TKE to a quasi-stationary state, while in the latter case there is an overshoot of TKE before the turbulence approaches quasi-stationarity.

Similar to the plots of $Re_r$ in Fig. 2(b), for C2 and C3, $k$ in Fig. 2(f) decays and then recover until it reaches quasi-stationarity, while $K$ monotonically increases until becoming quasi-steady as shown in Fig. 2(e). By contrast, in C4 and C5, $K$ increases initially, reaches a maximum and then decreases to a quasi-stationary state, while $k$ decays until $t^o \approx 4$ and then recovers and reaches a maximum at $t^o \approx 21$ for case C4 and $t^o \approx 24$ for case C5. After this time, the bulk flow decelerates and $k$ reaches quasi-equilibrium. While the minimum $k$ in the decay phase decreases with increasing stratification, the $k$ maxima in the recovery phase for cases C4 and C5 cases increases with stratification.

Time evolution of the friction and bulk Richardson numbers are shown in Fig. 2 (c-d). The $Ri_b$ and $Ri_r$ are inversely proportional to the bulk and wall scale kinetic energy. These plots show a trend opposite to $Re_b$, $Re_r$, suggesting that $Ri_b$, $Ri_r$ correlates to the conversion of kinetic energy to potential energy in mean and fluctuating fields, respectively.

The most stratified case C6 in Fig. 2 shows laminarization, as indicated by the sudden drop in $Re_r$, until $t^o \approx 15$ (as will be shown further below). We did not continue this case to achieve quasi-stationarity.

These results support earlier studies, that have used $h/L_{MO}$ to categorize the dependence of SBL turbulence on cooling rate. For $h/L_{MO} < 0.6$ (cases C2 and C3), turbulence is affected by stratification but continuously exists, similar to weakly stratified cases as in earlier works. For $h/L_{MO} \geq 0.6$ (cases C4, C5), in the recovery state, TKE achieves a larger peak than in the neutral case. For $h/L_{MO} \gtrsim 1$ (case C6), the energy-containing modes are strongly affected by stable stratification and laminarization is the dominant feature of the decay phase. However, there is uncertainty in the literature about exact crite-
The main focus of the present paper is case C5. However, we partly discuss other cases and in particular C6. The C2-C4 simulations are mainly presented to exhibit the overall effects of weaker stratification (compared to C5 and C6) on different phases of the cooling process.

**B. Identifying inner and outer regions**

To study the response of wall turbulence to surface cooling in the decay and recovery phases, we now identify how different layers (viscous sublayer, buffer layer, logarithmic, and outer layer) respond to different cooling rates.

In C5, because of the initially strong suppression of TKE, the wall-normal distances over which these layers are defined can be different from the neutral case. To see this discrepancy, consider Fig. 3, where $u^+$ are shown at different times during the surface cooling process for case C5. It is clear that the decay phase changes the viscous sublayer, such that parabolic behavior of this layer extends up to $z^+ = 15$ and buffer layer shrinks. However, log-linear behavior up to $30 \lesssim z^+ \lesssim 100$ is still observed, but with different constants in the log-linear profile at different times. By using mixing length theory and linear variability of length scales with respect to $z$ within the logarithmic layer, the turbulence production in the logarithmic region is closely related to the slope of the log-linear profile. However, while the slope is not significantly different at different times in Fig. 3, the constant in the log-linear profile at different times. By using mixing length theory and linear variability of length scales with respect to $z$ within the logarithmic layer, the turbulence production in the logarithmic region is closely related to the slope of the log-linear profile. However, while the slope is not significantly different at different times in Fig. 3, the constant in the log-linear profile varies substantially, suggesting that this coefficient is set by the details of other layers and not the logarithmic layer itself. Changes of slope of the log-linear profile between two successive times are smaller than changes of the additive constant of the log-linear profile between two successive times. The slope increases monotonically while the additive constant undergoes sharp changes. The mean velocity profile in the viscous sublayer and buffer layer at $t^o = 23.7$ are similar at $t^o = 42$, but the outer layer behavior is different. This difference in outer layer behavior...
suggests that the additive constant in the log-linear profile is set by the details of outer layer, similar to unstratified logarithmic layer.\textsuperscript{52}

To avoid the complication of the evolution of the viscous and buffer layers as the surface cools, we focus on the inner layer, where $z^+ \leq 100$, and outer layer, where $z^+ > 100$. This criterion separates the inner and outer regions at all times in Fig. 3 and is also valid for cases C2-C4 (no shown). With this splitting, we can analyze the differences in how the inner and outer regions respond to surface cooling.

C. Inner and outer layer response to surface cooling

Figure 4 shows the integrated TKE rate of change over the inner and outer layers scaled with their initial values in each of those layers for the decay and recovery phases. In this figure, $\langle dk_{av}/dt \rangle$ is the average TKE rate of change, where $\langle \rangle$ means time average of the quantity over the desired period. The subscript $av$ refers to layer over which integration of TKE is performed (i.e. inner or outer).

In the decay phase (Fig. 4a), it can be seen that for C2 and C3, the outer layer has the largest decay rate. However, as stratification increases, the difference between the decay rate in the inner and outer layers becomes smaller. Indeed, for C5, the inner layer has the largest decay rate, suggesting a possible collapse of near-wall turbulence. We will show later that for this case, near wall turbulence does collapses temporarily and the flow becomes patchy. In the recovery phase (Fig. 4b), the outer layer has the largest recovery rate but the difference between recovery rates of the inner and outer layers increases with increasing $Ri_\tau$. The logarithmic layer follows the trend of the near-wall regions as it becomes patchy. However, patchiness in the outer layer disappears after a few eddy turn over times as shown in Fig. 5(x).

D. Feedback process in C5 and C6

Turbulence in cases C2-C4 is continuously sustained. However, in C5 it becomes patchy soon after the beginning of surface cooling. As shown in Fig. 5, this patchy turbulence exists for about 10 eddy turnover times ($t^* \approx 10$) in the recovery phase until turbulence is eventually fully revived. Our main interest in this paper is to study features of the turbulence in the strongly stratified case C5. We present a detailed look at this case in this section. For comparison, we also consider the most strongly stratified case C6.

Horizontal snapshots of the streamwise velocity fluctuations for case C5 are shown at four vertical levels in Fig. 5 for different times during the cooling process. Shortly after the start of surface cooling at $t^* \approx 0.1$, near-wall streaks spread over the full horizontal plane, (Fig. 5a-c). Moving upward from the inner to outer layer, the streamwise aligned structures become more isotropic as shown in Fig. 5(d). During the decay phase, turbulence decays in all layers and, as shown in Fig. 5(e-g) at $t^* = 3.7$, the structures in the inner layer, and in particular near-wall streaks, disappear in some regions. Interestingly, laminar-turbulence coexistence is observed in Fig. 5 (e-g,i-k,m-o), with a turbulent strip of spanwise width $\lambda_y \approx 1.5h$ in the viscous sublayer and buffer layer. Turbulence is suppressed outside the strip. The turbulent strip becomes narrower in the early part of recovery at $t^* = 8.7, 14$ (Fig. 5i-j,m-n), decreasing to $\lambda_y \approx h$. Meanwhile, the fluctuations within the turbulent strip become stronger (e.g. streak velocities become stronger in Fig. 5(i,m) compared to Fig. 5(e)). The logarithmic layer also follows the trend of the near-wall regions as it becomes patchy. However, it has a wider turbulent strip.

As cooling of the surface continues, the patchiness eventually extends to the outer region at $t^* = 14.7$ as in Fig. 5(p), which strongly supports the necessity of inner layer production in sustaining outer layer turbulence. However, patchiness in the outer layer disappears after a few eddy turn over times as shown in Fig. 5(x).
FIG. 3. Mean velocity profiles for case C5 at early time $t^o = 0.1$ (solid), time of maximum decay $t^o = 3.7$ (dashed), end of recovery $t^o = 23.7$ (dash-dot), and stationarity $t^o = 42$ (dash-cross sign).

During the recovery in Fig. 5 (i-t), inner layer TKE builds up, although some patchiness still exists. The inner layer structures are fully recovered by $t^o = 23.7$. It will be discussed below that the quiet regions in the neighborhood of the turbulent strip in Fig. 5, which are often referred to as a laminar region, actually appear to consist of layered turbulence with flat structures.

Profiles of $k$ at different times in the cooling process are shown in Fig. 6. The decay, recovery, and approach to quasi-equilibrium can be seen in this plot. At early times $t^o \lesssim 3.7$, the TKE maximum shifts upward to $z^+ \approx 30$ as a result of the shrinking buffer layer and boundary layer growth, as shown by the mean velocity and temperature gradients in Fig. 7. At later times, the maximum TKE occurs around $z^+ = 15$, suggesting that the buffer layer is rebuilding. During the recovery phase, when TKE in the buffer layer starts to recover, TKE in the outer layer with $z^+ \gtrsim 300$ is still decreasing. This sequencing strongly suggests that there is a delayed recovery in the outer layer, which uses energy that has been produced ear-
FIG. 5. Fluctuating streamwise velocity $u' +$ at different layers and different times for C5. Each column shows a different level; from left to right, these are $z^+ = 3.5, 15, 70,$ and $300$. Each row shows a different time; from top to bottom, these are $t^* = 0.1, 3.7, 8.7, 14.7, 23.7,$ and $29.7$. Colorbars on each layer are based on $u' +$ for different layers at $t^* = 0.1$.

This delay in recovery is consistent with the discussion given in Sec. IV C.

The boundary layer thickness starts growing during the decay phase and it continues growing until $t^* \approx 13$ in the recovery phase as shown in Fig. 7. Mean shear at the wall and in the region $z^+ \lesssim 20$ is built up during the recovery phase. Therefore, this region may be responsible for turbulence production when sufficiently large tangential Reynolds stress is available. Both mean shear and mean temperature gradient acquire quasi-equilibrium at $t^* \approx 42$.

Profiles of the different contributions to the TKE budget are presented in Fig. 8 (see Appendix A). Except for the viscous sublayer, where viscous diffusion has large values, the main balance in the TKE budget at all times is between production and dissipation. The peak of buoyancy destruction at $z^+ \approx 100$ is an order
of magnitude smaller than the peak of production and dissipation. In the lower part of the viscous sublayer, the wall impermeability prevents turbulent production when \( z^+ \lesssim 2 \) at all times. Except for early times when peak production shifts upward as a result of boundary layer growth, dissipation dominates the inner layer outside of the buffer layer \( 5 \lesssim z^+ \lesssim 30 \), where production has larger values. Above \( z^+ \approx 100 \), production and dissipation are balanced. Production and dissipation are weakened during the decay phase \( 0.1 \lesssim t^* \lesssim 3.7 \), suggesting that the appearance of the patches results from a lack of production rather than an excess in dissipation. The impact of lack of production in turbulence collapse is also supported by experimental studies of SBLs.\(^{51}\)

Furthermore, tangential Reynolds stresses are suppressed in the decay phase (Fig. 9a) as a result of the damping effect of stable stratification, which leads to damping of vertical velocity fluctuations. Therefore, ejection and sweep events are hindered. This interruption in momentum transfer can also be seen in \( T^+ \), Fig. 8(d), where upward TKE transfer is almost fully suppressed and downward TKE transfer is significantly reduced. This is expected since once fluid in the near-wall region becomes heavier as a result of surface cooling, more energy is required for vertical motions. The buoyancy frequency has larger values as we approach the wall due to the thermal boundary condition (Fig. 7), and therefore fluid closer to the wall feels a stronger restoring force. Pressure-work has its largest value in lower part of viscous sublayer at all times.

Figure 10 shows streamwise velocity fluctuations for case C6. This figure reveals that for the strongest surface cooling, while turbulence in the inner region is damped in Fig. 10(e-g,i-k), the outer layer (Fig. 10h,l) still has active turbulence (although the intensity of the fluctuations is strongly reduced). The surviving streaks at
time $t^o = 3.7$ in the buffer region (Fig. 10f) are of size $\lambda_x \approx L_x$, suggesting they are associated with the largest modes that the computational domain can handle. Structures similar to the streaks in buffer region (with higher intensity) exist in the logarithmic layer for this time. The buffer and logarithmic layers also shows analogous large scale features. In this case, the near wall streak intensities are an order of magnitude smaller than those in case C5 at the same time. The inner and outer layers are almost decoupled. The diffusive nature of the inner region for case C6 is also clear. Continuing surface cooling leads to complete removal of quasi-streamwise structures and continuous decrease of intensity of fluctuations. By time $t^o = 14$, outer layer turbulence is also damped.

### E. Feedback mechanism in C5 and C6

In this section, we discuss possible mechanisms that may explain the response of the flow to the surface cooling described in the previous section. We first visualize the change in flow structures with cooling. We use the Q-criterion, which is the second invariant of the velocity gradient tensor, which is defined as

$$\dot{Q} = -\frac{1}{2} \frac{\partial u_i}{\partial x_j} \frac{\partial u_j}{\partial x_i}. \tag{12}$$

Figure 11 shows $Q$ at $t^o = 0.1$. At this early time, turbulence spans whole cross-section and the near wall region ($z^+ \leq 30$) is dominated by quasi-streamwise vortical structures. Lifted-up vortices from these quasi-streamwise vortical structures are also present and are sur-
rounded by other incoherent structures aloft. These near-wall structures contribute to sweep and ejection events associated with pulling high-momentum fluid from upper levels and pushing low-momentum fluid to upper levels, creating velocity streaks and maintaining turbulence. However, as shown in Figs. 5 and 10 stable stratification can change the organization, population, and intensity of these structures.

Figure 12 shows $Q$ at a later time $t^o = 11$, in the early stage of the recovery phase. Contour plots of the total kinetic energy are also included to indicate energy transfer. The modulation of vortical structures caused by stable stratification is clear. The quasi-streamwise vortical structures are absent in the regions outside of the turbulent strip, which we refer to as quiet zones. Turbulence is concentrated in the strip, which comprises numerous quasi-streamwise vortices and hairpin like structures\textsuperscript{56,57}. However, the quantity of lifted and detached vortices is considerably lower in comparison with $t^o = 0.1$, even in the turbulent strip which can explain the reduction in turbulence production from its initial value. This modulation can also be seen in the contour plots of the total kinetic energy in Fig. 12, where vertical transport of lower to higher momentum from the inner to outer layer is significantly altered. Boundary layer growth up to $z^+ \approx 300$ can be seen from these contour plots along with shear instabilities at the top of the boundary layer.

An important question is how turbulence recovers from the patchy state in C5. Different scenarios may be considered for this recovery: it could be due to spread of the turbulent strip in the spanwise direction as a result of built-up of shear and tangential Reynolds stress as the front of the turbulent strip destabilizes the neighboring quiet region\textsuperscript{58} leading to spreading of turbulence in spanwise direction, and/or it could be excitation from large scale eddies aloft that can trigger transition and cause recovery. Hairpin-like vortices\textsuperscript{59} are observed in Fig. 12 at $y^+ \gtrsim 1500$ in the near-wall region for $x^+ \gtrsim 2000$ and $x^+ \approx 3500$. This hairpin vortex is 200 wall units in spanwise direction away from the turbulent strip, which is consistent with the scenario based on excitation from the boundary layer top. On the other hand, if the recovery is independent of fluctuations at the boundary layer top, then turbulence in the quiet region should be recovered in the absence of those fluctuations.

To test this hypothesis, we perform two experiments in which we remove the fluctuations at certain heights from the right-hand side of the governing equation by replacing the terms in Eq. 3-4, with their horizontal average. The fluctuations are removed above $z^+ = 200$ in the first experiment and $z^+ = 300$ in the second. Both experiments are initialized using fields from C5.
at time $tu_r/h = 3.7$ associated with maximum decay. Time series of domain integrated MKE and TKE are shown in Fig. 13 for these two experiments. These plots reveal that while MKE is essentially the same in both experiments, the presence of fluctuations at $z^+ \gtrsim 300$ is important for recovery from localized patch such as a turbulent strip. This finding supports the hypothesis that recovery in the quiet regions is triggered by large structures in the outer layer rather than spreading of the strip.

Thus the recovery process in C5 can be understood as follows: Once turbulence reaches maximum decay in the inner layer, energy-containing eddies in the outer layer still use TKE that has been produced in the buffer region at previous times (which had higher TKE) due to delay in the decay of the inner and outer layer. These outer layer eddies can control decay of inner layer TKE from further fall-off through interaction of inner and outer layers where large scale eddies of the size of $\lambda_z^+ \approx 300\ (\gtrsim h/2)$ in the outer layer can penetrate down close to the wall and stir the flow (in the sense of Townsend’s wall attached eddies hypothesis\(^39\)).

Active eddies in the turbulent strip in the buffer layer will continuously maintain turbulence in the log and outer layers. However, since these eddies lose a significant portion of their TKE during the decay phase, the outer layer will not be maintained sufficiently and will experience decay at a later time.

Excitation of inner layer turbulence by outer layer sweeping in the decay phase helps to reinvigorate the regeneration cycle of near-wall turbulence\(^60\). Then, streaks in the viscous sublayer and buffer layer reappear, reactivating ejection and sweep events in quiet regions near the wall. Eventually, turbulence spans the whole channel width and fully recovers. While
FIG. 11. Visualization of instantaneous scaled $Q'^+$ at time $t^+=0.1$ as an indication of vortical structures for case C5 colored by distance from the wall. Cross-sectional slices are total kinetic energy in streamwise and spanwise planes. Both $Q'^+$ and total kinetic energy are scaled with their maximum values. Isosurfaces of scaled $Q'^+$ are plotted at the level of 0.01. Colorbar is based on values of scaled total kinetic energy.

TKE is building up in the inner layer, a smaller amount of production from the inner layer is needed for outer layer recovery, and therefore the outer layer recovers faster due to fact that the effect of viscosity is less significant there.

The most stratified case C6 is different. Figure 14 shows $Q$ for C6 at a later time $t^+=23.7$. It can be seen that the cooling process leads to a collapse of the vertical scale in the vortical structures in the inner region, and leads to the formation of quasi-flat structures. The flat structures are also observed in the outer layer. As shown in Fig. 10, elongated streamwise structures are replaced by these flat pancake-like structures.

In the stably stratified ABL, intermittences such as local patches of turbulence also exist under strongly stable stratification. A similar recovery process to what we have discussed in this section has also been suggested in field studies of the stable ABL. These studies suggest that the patchiness in strongly stable ABLs could be interrupted through the intrusion of shear instabilities from the boundary layer aloft into the stable surface layer.

F. Nature of quiet zones in C5

In this section, we consider the characteristics of quiet regions adjacent to the turbulent strip that appear during the cooling process in C5. To do so we investigate the spectra of the streamwise velocity fluctuations.

The one-dimensional longitudinal spectra of streamwise velocity, averaged over $y$ at $z^+=15$, are shown in Fig. 15. Spectra are averaged in $y$ over regions that become quiet during the decay and recovery phase. As expected, initially, the spectrum shows an approximate $k_x^{-5/3}$ behavior over $10 \lesssim k_x h \lesssim 100$, where $k_x$ is the streamwise wave number. During decay as shown in Fig. 15(b), the spectrum become steeper over these wave numbers as turbulence
is suppressed. The slope of the spectrum increases in the recovery phase as shown in Fig. 15 (c,d). However, for about 5 eddy turnover times the slope of the spectrum is approximately $-5$ as shown in Fig. 15 (c,d), similar to viscously coupled stratified turbulence. In the logarithmic region, the steepening of the spectrum is weaker compared to the near-wall region and the slope of spectra becomes approximately $-3$ as shown in Fig. 16(a-f). The smallest wavenumbers present $k_{x}^{-1}$ behavior initially (Figs. 15a and 16a), and once turbulence is recovered (Figs. 15e-f and 16e-f).

The behavior of the spectra suggests that the quiet regions may consist of viscously layered pancake vortices, where vertical fluctuations are strongly suppressed by stable stratification and the vertical scale of the eddies is set by viscosity. In this regime, the Ozmidov scale is smaller than the Kolmogorov scale, where the Ozmidov scale is defined as $L_o = (\epsilon/N^3)^{1/2}$. The buoyancy Reynolds number, which is related to the ratio of Ozmidov to Kolmogorov scales, is defined as

$$Re_B = \left( \frac{L_o}{\eta} \right)^{3/4} = \frac{\epsilon}{\nu N^2},$$

(13)

where $\eta = (\nu^3/\epsilon)^{1/4}$ is the Kolmogorov scale. $Re_B$ can be used to detect regions of viscously coupled pancake vortices: regions where $Re_B \ll 1$ correspond to viscously layered vortices, and regions where $Re_B \gg 1$ contain overturning and small scale vortices. Plots of horizontally-averaged $Re_B$ in the quiet regions and the turbulent strip are shown in Fig. 17. At $tu_r/h = 0.1$, these two regions have the same $Re_B$ due to spanwise homogeneity of the turbulence at this time. For both of these regions, $Re_B > 1$ where $z^+ > 10$. At later times, until turbu-
FIG. 13. Time series of (a) domain averaged MKE and (b) domain averaged TKE for C5 experiments where fluctuations are removed above $z^+ = 200$ (blue lines) and $z^+ = 300$ (red lines). MKE and TKE have been scaled by their initial values. Time zero here corresponds to $tu^*/h = 3.7$ in Fig. 2.

In Ref. 7, a Dirichlet boundary condition for temperature was used at the upper boundary. In their $Re_B = 1120$ simulation initialized from a neutral case, only the experiment perturbed with 5 percent higher-than-average TKE in the outer region could recover. Here, we observed that C5 can recover from partial collapse without perturbations to the initial condition. This suggest the SBL upper boundary condition can play an important role when strong cooling from the bottom surface is imposed. To investigate this, we carried out another simulation with initial condition and parameters identical to C5, but with a Dirichlet boundary condition ($\theta = 0$) at the upper boundary (case C5D). In Fig. 18(a), a time series of the domain-integrated TKE for this case is shown and compared to that from C5. Although heat entrainment from the upper boundary leads to a decrease in decay rate up to $t^o \approx 4$, the time of recovery in C5, the C5D case continues decaying after this time. This finding strongly suggests that the impact of the upper boundary condition on outer layer dynamics influences recovery, since (as shown earlier) recovery in C5 is strongly linked with outer layer large-scale structures. It should be pointed out that in C5D, turbulence become patchy as well shortly after introducing stratification. Nevertheless, by $t^o \approx 6.8$ near-wall streaks disappear in C5D as decay continues. For example, the value of TKE at $z^+ = 15$ becomes almost two orders of magnitude smaller than C5 at same time, as shown in Fig. 18(b). The shift in TKE for C5D toward higher $z^+$ is likely a result of laminarization, where wall shear is strongly reduced and the boundary layer cannot accommodate a buffer layer. In laminarization of the boundary layer, the buffer layer is not capable of sufficient turbulence production to overcome dissipation caused by viscosity. Thus, the energetic eddies are located farther from the wall since viscous dissipation is reduced moving from the wall to-

G. Effect of upper thermal boundary condition

The results shown thus far were obtained using a neutral boundary condition for heat transfer from the upper boundary of the SBL. If
FIG. 14. Visualization of instantaneous $Q^+$ criterion at time $t^* = 23.7$ as an indication vortical structures for case C6 colored by distance from the wall. The $Q^+$ is scaled with their maximum values. Isosurfaces of scaled $Q^+$ are plotted at the level of 0.01. Colorbar is based on distance from the wall.

V. CONCLUSION

In this paper, the response of wall turbulence to strong surface cooling was studied using high-resolution DNS. It was shown that the cooling process can be divided into different phases depending on the cooling rate. Turbulence first undergoes decay regardless of the imposed cooling rate. However, recovery largely depends on the cooling rate. For a weaker cooling rate, turbulence is ubiquitous at all vertical levels, consistent with previous studies\textsuperscript{20,21}. In this situation, TKE recovers to a level comparable to the neutral case. For stronger cooling rates, TKE reaches values during recovery that are higher than those in the neutral case. In these strongly stratified cases, turbulence may collapse partially with the SBL turbulence becoming patchy, or turbulence may collapse totally.

For patchy turbulence ($Ri = 1120$), it was shown that during decay, the viscous sublayer grows to $z^+ \approx 15$ and the buffer region shrinks as the boundary layer grows. However, logarithmic behavior is observed up to $z^+ \approx 100$ at all times, with slope and additive constants that depend on time.

For $Ri = 1120$ (case C5), a thorough analysis of the TKE budget confirms that the dominant balance is between production and dissipation at all times. It was shown the appearance of patchiness is due to a significant reduction in turbulent production (due to direct impact of stable stratification on tangential Reynolds stress), and not excess dissipation. This reduction in production is then linked to a decrease in the population and intensity of quasi-streamwise vortical structures. During decay and part of the recovery phase, a quiet region appears in the near-wall region with width between $[1 - 1.5]h$.

It was shown that the quiet regions outside of the turbulent strip actually resemble viscously layered stratified turbulence, with layered vor-
FIG. 15. Longitudinal spectra of streamwise kinetic energy $E_{uu}(k_z)$ at $z^+ = 15$ at different times in subbox corresponding to a quiet region at maximum decay, which is $5\pi/6 \leq y/h \leq \pi$. Times correspond to (a) $t^\ast = 0.1$, (b) $t^\ast = 3.7$, (c) $t^\ast = 8.7$, (d) $t^\ast = 14$, (e) $t^\ast = 23.7$, and (f) $t^\ast = 32.9$, respectively. Magenta, blue, red, and green lines have slope of -1, -5/3, -3, and -5, respectively.

In the most stratified case with $Ri = 2800$ (case C6), the inner layer turbulence is completely suppressed and the outer layer turbulence decays subsequently, leading to the formation of flat structures in the near-wall region.
and pancake-like vortices in the outer layer.

The recovery of turbulence in C5 is discussed in detail. One might say for this Richardson number ($Ri = 1120$) the autonomous cycle of near-wall turbulence, where turbulence in the near-wall region can autonomously sustain itself without intervention of eddies from the core region, is partially or totally hindered in the decay phase by the action of strongly stable stratification. In C5, however, the outer layer large scales of size $\lambda_z^+ \gtrsim 300$ have enough intensity to excite the partially damped turbulence in the inner layer, which can restart the inner layer regeneration cycle. In C6 ($Ri = 2800$) this autonomous cycle of near-wall turbulence is suppressed completely as near-wall streaks are damped soon after starting the cooling process.

The effect of higher Reynolds number, Richardson numbers, and larger domain size on the characteristics of the patchy state, the evolution of TKE and vorticity, and possible turbulence recovery will be the subject of future work. These simulations can improve our understanding of the more realistic SBL, in particular once turbulence becomes intermittent for strongly...
stable stratification. Moreover, in future work, it could be interesting to explore non-OBA effects on strongly-stable stratified wall-bounded flow by solving the Navier-Stokes equations under the low Mach number approximation.
